Abstract

Recent advancements in statistical methods, colloquially termed as machine learning, have revolutionized a tremendous number of fields due to the ease by which we can train models that are flexible enough to regress to data of interest while maintaining predictive power. Nowhere has this impact been felt as much as in the field of materials science, which had previously been bottle-necked by relatively computationally expensive methods. Herein, we report on a ML methodology to enumerate bulk crystal structures in the IrO_2 and IrO_3 space.

Introduction

The general problem of solving for the most thermodynamically stable crystal structure for an arbitrary inorganic system remains a prohibitive challenge in material science. Experimentally synthesized inorganic materials often conform to the globally minimum energy struc-

ture (or similarly stable meta-stable phases), therefore it is desirable from a computational perspective to know the corresponding crystal structure to conduct simulations on. This problem is theoretically challenging, as the number of possible crystal structures for a given stoichiometry is prohibitive. Iterative Active Machine Learning and unique prototype identification to discover stable new materials and catalysts. Motivation for IrO_x , low representation, longstanding controversy over oxidation states and topology, and demonstrates promise for OER and Li ion batteries.

Reported +6 oxidation state phases are achievable leading to high degree of structural variability, which is the highest for transition metals. High oxidation states (low pH high anodic voltage, harsh oxidizing conditions) unexplored, need very specific structures with precise oxygen connectivity (aka high pressure SrIrO_3) that can exist. Machine learning is the efficient way to explore this exploring Antarctica for life sparse space. What we show here...

The two key features of our algorithm that make the exploration of an expansive space pos-

sible are its use of surrogate models and active learning framework. Because DFT calculations are prohibitively computationally expensive to carry out for large data sets, herein we train a Gaussian Process (GP) machine learning model to serve as a surrogate model. In general active learning applications, the requisite training data is not available. Active learning frameworks are a means by which to generate the most valuable training data set, on the fly.

Results and discussion

I. Active Learning Machine Learning Methodology

The structures that comprise the candidate data set were constructed by parsing for structurally unique systems in the OQMD and Materials Project DFT databases. The structural uniqueness was performed using a space-group symmetry classification scheme developed by¹ TEMP-Ankit-REF which can classify any arbitrary structure based on stoichiometry (composition), space-group, and Wyckoff positioning of the atoms (see SI for more details on the structural classification scheme). To focus the scope of the study, only AB₂ and AB₃ stoichiometries were parsed from the databases. The AB₂ formula was chosen because it includes rutile-IrO₂, the known most stable polymorph of IrO₂. Importantly, AB₃ was chosen to include high valency IrO₃ structures in our search. This classification scheme can directly serve as a fingerprinting scheme and has successfully been used for the prediction of formation energies. The results of the classification scheme resulted in a XYZ AB₂ and XYZ AB₃ structural prototypes for which iridium and oxygen were replaced for A and B sites, respectively. Finally, a coarse isotropic volume relaxation based on atomic radii was performed on the structures to accommodate the atomic radii of iridium and oxygen into the lattice. Finally, a Voronoi tessellation based fingerprinting scheme developed by Wolverton-paper-REF was used to encode the relevant chemical information for each structure. The Voronoi based method was used

because it is insensitive to volume relaxation. PCA was used to reduce the dimensionality of the feature space from 271 to 20 features such that 99percent of the variance is captured.

The active learning algorithm proceeds through iterative ML training, prediction, and acquisition steps and is visualized in figure TEMP. The A Gaussian process (GP) regression employing a rational quadratic kernel was chosen as the ML model because it offers a high degree of flexibility and importantly, error quantification for the predicted formation energies. Further details on the GP model, including hyper parameter information, is including in the SI.

1. Candidate space of structures is generated
2. Initial seed data is used to train a ML model
3. ML model predicts energy of entire candidate space
4. Most valuable calculation(s) is selected using acquisition function
5. DFT calculation(s) is(are) performed to obtain additional training data points
6. ML model is retrained with additional data
7. Repeat steps (TEMP) through (TEMP) until convergence criteria is reached

[Figure 1 about here.]

II. Application of AL to stable polymorph discovery in the Ir-O space

- Describe relevant features - Physical intuition? - Describe convex hull plot (energy vs. Ir-O distance), computed amorphous phase to define synthesizability - While only 2 IrO₂ in MP/OQMD, we can compare our structures to other computed IrO₂ not in open databases.

This is a citation example.²

[Figure 2 about here.]

- XYZ unique AB3 Structures, 259 unique prototypes. Substitute Ir and O, expand to minimum Ir-O distance ζ XYZ - followed same procedure as in 3.1, Training Set of 35 structures, 8 of which are IrO_3 - Describe initial training and training after first 10 DFT structures

- Describe convex hull, classes of structures (α - AlF_3 like, rutile like, and layered, should be segregated in hull plot) - briefly describe structures within each class, cite in literature where appropriate

[Figure 3 about here.]

III. Electrochemical OER Application

In the following section we will demonstrate the merit of our stable polymorph discovery algorithm by elucidating the electrochemical properties of the four promising structures discussed in the previous section. In particular, surfaces constructed from the four polymorphs will be evaluated for their activity towards the oxygen evolution reaction (OER), an important chemistry with direct application to fuel cell devices. Additionally, the surfaces will be evaluated for their stability and equilibrium surface coverage of surface oxygen and hydroxides.

Bulk Pourbaix

The electrochemical stability phase diagram (E vs. pH) was constructed by considering the equilibrium conditions of the following species: Ir, rutile- IrO_2 , α - IrO_3 , rutile- IrO_3 , β - IrO_3 , and an aqueous dissolved $\text{IrO}[4-]$ species (See TEMP—SI for additional details). The resulting diagram is shown in Fig. S4. Importantly, under acidic conditions (pH < 7) and in the bias region of interest for the OER (1.23 V vs. RHE) α - IrO_3 shows a large window of stability. This indicates that the α - IrO_3 phase may be stabilized under the highly oxidizing conditions of the OER. For comparison, the stability regions of the metastable rutile- IrO_3 and β - IrO_3

phases, in the absence of any other competing IrO_3 polymorphs, are indicated by unfilled solid lines. As shown, these metastable phases appear to also have a wide region of stability in the OER region, due to their formation energies being within TEMP eV of the globally stable α - IrO_3 phase, see SI table TEMP for the bulk energies of all considered phases. Because of their similar energies it is possible that some or all of these IrO_3 phases may be present and relevant for the OER. In the next section, we explore this possibility by computing the theoretical OER activity of these polymorph systems.

[Figure 4 about here.]

b. OER Activities and Surfaces

Fig. S5 summarizes the major results of the electrochemical activity and surface stability analysis. First, Fig. S5 a.) shows the surface energy Pourbaix plots for the four IrO_x crystals of interest. For each bulk system, the surface energy as a function of applied potential (pH=0), for various facets, and at various coverages (bare, $\ast\text{OH}$, and $\ast\text{O}$ covered), are shown, see SI for more details. The specific facets were chosen from the highest intensity x-ray diffraction peaks from powder-diffraction spectra simulated in VESTA, as well as using physical intuition as to which facets would be most physical. Additionally, the bulk phase limits of stability from figure TEMP are included at the bottom of each subplot. In most cases, the oxygen covered surfaces dominate at the OER equilibrium potential (1.23 V vs RHE) with bare surfaces being competitive to within TEMP eV/ \AA^2 , this competitiveness goes away at even modest overpotentials (eta 0.3, \sim 1.5 V vs RHE), at which point the oxygen covered terminations are further overstabilized relative to the bare surfaces, making them the sole dominant termination. Therefore in our activity analysis we consider mainly oxygen terminated surfaces for the OER. The OER activity (expressed in terms of the limiting potential) for select oxygen terminated surfaces are shown in Fig. S5 as a function of the DGO-DGOH TEMP OER thermodynamic descriptor.

The two rutile-IrO₂ surfaces (100, and 110) are located towards the strong binding side of the volcano, indicating that they bind OER intermediate too strongly. Encouragingly, with predicted overpotentials of TEMP and TEMP, our rutile-IrO₂ are within the range of experimental overpotentials found in literature. The three IrO₃ polymorph surfaces all have DGO-DGOH descriptor towards the top and right of the volcano, indicative of weaker binding energetics. This is evident from figure SI TEMP (scaling) which shows a clear distinction between the IrO₂ and IrO₃ polymorphs, with IrO₃ binding on average TEMP eV weaker than IrO₂. The best performing systems, including the (100), (110), and (211) facets of a-IrO₃, b-IrO₃ (101), and R-IrO₃ (110), have overpotentials of 0.4 V vs RHE, a 0.2 V vs RHE improvement over the rutile-IrO₂ system. We note that the computed overpotentials for our rutile-IrO₂ system differs from that reported in REFERENCE *Colin science by 0.2V. This discrepancy is due to our use of spin-polarization, which was neglected in Seitz et al., which strengthens the binding of IrO₂.*

[Figure 5 about here.]

c. OER Intermediate Scaling

Figure TEMP shows the scaling relations between the adsorption free energies of the OER intermediate species for the IrO_x systems studied herein. It can be seen clearly that the data points corresponding to the three IrO₃ polymorphs are roughly 1 eV weaker binding than the rutile-IrO₂ points. This generally weaker binding of the IrO₃ stoichiometry is responsible for the observed improvement in theoretical activity. The ΔG_{OOH} vs. ΔG_{OH} relationship is very close to the traditional “universal scaling relations”, demonstrating that our materials do not break the infamous ΔG_{OOH} vs. ΔG_{OH} scaling.

[Figure 6 about here.]

Conclusion

And in conclusion we presented work here...

Electrochemical OER Computational Methods

Density Functional Theory Methods

All OER calculations were performed using density functional theory (DFT) implemented via the Vienna ab-initio simulation package (VASP) and utilizing the PBE exchange-correlation functional. Dipole corrections were imposed on all non-symmetric slabs. A $4 \times 4 \times 3$ k-point mesh with gamma-point centered Monkhorst-Pack was used for all slabs. The plane-wave energy cutoff was 500 eV.

All slab calculations maintained a vacuum spacing of ≥ 15 Å. All structures were relaxed utilizing a TEM algorithm with a stop criteria being that all atoms satisfy a maximum force threshold of 0.02 eV/Å.

OER Thermodynamic Methodology

Surface Energy Pourbaix Methodology

Surface energy Pourbaix plots were constructed by calculating the surface energy of each slab by under standard conditions ($V=0$ and $p_H=0$) and then utilizing the computational hydrogen electrode to compute the potential dependence of the surfaces.

Surface energy calculations were performed for various facets for slabs of increasing thickness. The bulk energy was then extracted by fitting the total energy of the slabs against the number of layers as explained in REF2. This was done to avoid common issues of surface energy divergence associated with using a separate bulk energy calculation.

The sensitivity of a given slab to an applied bias is dependent on the composition of the sur-

face, in particular, the effect of coverage of electrolyte species which can deposit oxygen, hydrogen, and hydroxide species on the surface layers. These additional O and H atoms are not referenced to the atoms in the slab, but are instead referenced to the computational hydrogen electrode and water-splitting reaction. The equation for is as follows:

Procedure: - For the top/most stable bulk structures the following procedure was carried out

- * Stable stoichiometric terminations were cut from the bulk. Stable termination planes were guesstimated via intuition, and the x-ray diffraction pattern tool from Vesta

- * Electrochemical surface coverage was elucidated via a surface Pourbaix analysis. Need to know the coverage of surface under operating conditions (~ 1.23 V RHE)

- * Thermodynamic/limiting potential analysis of the OER mechanistic pathway. Volcano plot, limiting potentials, etc.
